## Abstract

Despite decades of work, Duchenne Muscular Dystrophy (DMD) remains a deadly disease with no cure. Recent advances in stem cell biology, immunology, and bioengineering suggest an interdisciplinary approach to the treatment of DMD. Towards this end, we created a multifunctional hydrogel composed of hyaluronic acid and skeletal muscle extracellular matrix that is cytocompatible, injectable, and biodegradable. The hydrogel facilitates the controlled release of myostatin inhibitors *in vitro* and increases their bioactivity *in vivo*. The hydrogel also promotes macrophage polarization towards CD206 expression, elevates anti-inflammatory cytokine levels, and co-injection of hydrogel with myostatin inhibitor yields a significant increase in Foxp3<sup>+</sup> regulatory T cells. Finally, human embryonic stem cell derived myoblasts transplanted with the hydrogel demonstrated greater survival at 7-10 days post-injection, and increased engraftment after 4 months in immunodeficient dystrophic mice. Overall, this study represents a promising advance in regenerative medicine therapies for DMD.

## Acknowledgements

To Kathryn and Jennifer, for your guidance, mentorship, insight, and patience.

To Kaitlyn for introducing me to the world of immunology, Matt and Liam for helping me analyze endless FACS samples, Shoumyo for helping with rheology, and everyone else in the Elisseff lab for being awesome.

To Lindsay, for being the best undergraduate mentee a grad student could ever ask for. To Tracy and Naili for teaching me how to cryosection and harvest muscle, to Jyothi for correcting me, and everyone else in the Wagner lab for being awesome.

To Colleen, Leslie, Rajini, Bob, and everyone else in the CMM program for giving me the opportunity to train at such an amazing place.

To my CMM Class of 2011, and everyone I've met at Hopkins, it's been a wonderful journey. To all those still in the process – you'll get there soon!

To Edith, Dan, and Sorin for introducing me to the world of biomedical research. Thank you for taking your chances on an inexperienced undergraduate!

To BDCP, Project D, imPulse, and the greater urban dance community for giving me a second life outside of science, and friends no matter where I go.

To all my friends from Kindergarten to College, for always being there for me.

To Mom, Dad, Tita, Jeff, and Sheryll, thank you for instilling and supporting my love for science since childhood. I literally wouldn't be here without you.

To Jean, for everything. I love you with all of my heart, and look forward to us forever.

## **Chapter 1: Introduction**

## Overview

In **Chapter 1**, I will introduce Duchenne Muscular Dystrophy (DMD), current and future treatment options for DMD including cell therapy and myostatin inhibition, the role of the immune system in skeletal muscle repair and regeneration, and the application of biomaterials and regenerative medicine principles to skeletal muscle. **Chapter 2** describes the synthesis of the materials utilized in this study, the fabrication of an injectable biomaterial-based hydrogel, and its initial characterization *in vitro* and *in vivo*. Cytocompatibility, biocompatibility, and growth factor delivery are assessed. **Chapter 3** characterizes the effects of the hydrogel and myostatin inhibitor on the local immune microenvironment in dystrophic mice, in terms of immunofluorescence visualization, cytometric characterization of local cell populations, and cytokine expression. **Chapter 4** describes work characterizing human pluripotent stem cell derived skeletal muscle myoblasts and the application of the hydrogel to skeletal muscle cell therapy. Finally, **Chapter 5** presents the conclusion of this work and describes potential future experimental directions for this project.

## **Duchenne Muscular Dystrophy (DMD)**

Skeletal muscle disorders pose a significant public health burden, decreasing the quality of life of hundreds of thousands of patients worldwide [1]. The most common of these disorders is Duchenne Muscular Dystrophy (DMD), an X-linked recessive disease which affects approximately 1:5000 boys annually [2]. Due to mutations in the dystrophin gene, DMD patients have a complete absence of the dystrophin protein, which has key structural and signaling roles [3]. Without dystrophin, skeletal muscle undergoes a constant cycle of degeneration and regeneration, ultimately leading to replacement with fat and fibrotic tissue [4]. Depending upon genetic and environmental factors and standard of care, DMD patients generally lose the ability to ambulate as children, progressing to loss of upper limb function, and death by early adulthood due to cardiomyopathy and/or respiratory failure [4].

Dystrophin is one of the largest genes in the human body, consisting of 79 exons and 8 promoters [5] encoding a 427 kDa protein [6] that links the skeletal muscle sarcolemma to the underlying extracellular matrix through an N-terminal actin-binding domain, a cysteine-rich sarcoglycan-binding domain, and a C-terminal dystroglycan binding domain, all linked with a rod domain [7]. A variety of mutations can occur within the dystrophin gene, including missense [8] and nonsense [9] mutations; roughly 60% of mutations in DMD occur between exons 45-55 [10] and all have the potential to severely compromise the concentration and overall function of dystrophin. The dystrophin linkage is key to maintaining the complex architecture of skeletal muscle and

its ability to transduce force; absence or malfunction of dystrophin leads to a loss of stability between skeletal muscle and basal lamina, resulting in breakdown of components of the dystrophin glycoprotein complex, mis-localization of key proteins such as neuronal nitric oxide synthase, and compromise of the integrity of the sarcolemmal membrane [7], ultimately leading to ineffective skeletal muscle repair [4].

## **Treatments and Therapies for DMD**

Duchenne patients are typically maintained on corticosteroids such as prednisone [11] and the recently-approved deflazacort [12] whose mechanism of action in this disease is not entirely understood but likely results in modulation of local inflammation. However, as of 2017 two therapies to promote restoration of Dystrophin have received regulatory approval. Restoring even low levels of Dystrophin has the potential to confer clinical benefit, recapitulating the symptomatic profile of Becker Muscular Dystrophy, a less severe disease characterized by reduction of functional dystrophin but maintenance of some dystrophin function [13]. Ataluren, a compound designed to promote read-through of premature stop codons [14] caused by nonsense mutations in the dystrophin gene, was approved by the EMA [15] despite a lack of consensus over the efficacy of the drug as determined by uncertainty over the use of luminescence-based assays to measure its effectiveness [16]. Eteplirsen, an agent designed to promote exon 51 skipping and restore the reading frame of dystrophin [17], was also approved by the FDA [18] for use in DMD patients [19]. Despite the approval of these therapies, they appear to provide only a small benefit and are far from a cure [20].

Several other therapies for DMD are currently in various stages of development [20]. Dissociative immunomodulators such as VPB15 stabilize the sarcolemmal membrane and mediate inhibition of NF- $\kappa$ B without nonspecific immunosuppression, ameliorating DMD symptoms [21]. Several evaluated compounds upregulate the expression of compensatory proteins such as utrophin and biglycan that confer membrane-stabilizing functions. One modulator of utrophin, an autosomal analog of Dystrophin which maintains similar functions and can mediate disease severity in animal models of DMD [22], has recently completed phase I clinical trials [23]. Recombinant human biglycan, an ECM protein which has been shown to recruit the dystrophin glycoprotein complex proteins dystrobrevin, syntrophin, and neuronal nitric oxide synthase [24] as well as utrophin [25] to the sarcolemmal membrane, is also approaching clinical evaluation.

Gene therapy approaches to replacing or editing non-functional Dystrophin have benefited from recent significant advances in molecular biology, particularly with the use of adeno-associated viral vectors (AAVs) [26]. Despite the 4.7 kb packaging limit of AAVs, micro- and mini- Dystrophin constructs [27] with truncated rod domains but functional N- and C- termini can be delivered via AAVs to treat dystrophic mice [28]. Micro-dystrophin therapies are currently undergoing industrial development for eventual clinical application [29]. Alternative strategies utilize AAV-mediated delivery of the CRISPR-Cas9 genome editing system, a highly specific prokaryote-derived mechanism that can readily edit genomic DNA [30, 31]. Several groups have utilized this system to treat dystrophic mouse muscle [32, 33] and local muscle progenitor cells [34],

and utilized targeting vectors for muscle-specific delivery [35]. In addition to virally mediated gene editing and replacement, one additional strategy to replace Dystrophin has undergone significant development— cellular therapies.

## **Cellular Therapies in DMD**

Young, healthy skeletal muscle has an enormous capacity for regeneration from resident and circulating myogenic precursor cells [36]. The primary progenitor population consists of Pax7+/MyoD- satellite cells (SCs), which are located between the basal lamina and the sarcolemma of individual muscle fibers. These cells remain quiescent until stimulated to divide by cytokines or growth factors released during muscle injury [37]. Satellite cells divide asymmetrically, with one daughter cell repopulating the SC niche and the other undergoing either myogenic differentiation (expressing MyoD, Myf5, myogenin, and MRF4), or transdifferentiating into adipocyte or fibroblast lineages in ineffective regeneration [38, 39].

Cell based therapies, which involve transplanting healthy skeletal muscle progenitor cells into diseased muscle, are widely considered as a potential treatment for DMD. Preclinical trials have demonstrated that transplanted muscle progenitor cells integrate with existing muscle, restoring the dystrophin protein in dystrophic mice [40] and dogs [41]. Notably, an alternative strategy involving the transplantation of bone marrow derived stem cells has also been used to restore dystrophin in dystrophic mice [42]. Dystrophin-deficient muscle progenitor cells derived from induced pluripotent stem

cells corrected *ex vivo* via micro-utrophin delivery [43] or CRISPR-Cas9 editing [44] have also been used to restore Dystrophin *in vivo*. Consequently, several cell types have been tested in various clinical trials, ranging from donor myoblasts from a father into affected progeny [45] to vessel-associated mesoangioblasts [46]. However, these trials have all failed to produce clinically significant outcomes [47]. The majority of transplanted muscle progenitor cells do not survive transplantation, and those that do are introduced into a fibrotic environment that inhibits their proper differentiation, integration, and maturation into myofibers [47].

## **Role of Myostatin Inhibition in DMD**

One class of compounds that has undergone significant development includes inhibitors of myostatin, an endogenous TGF- $\beta$  family member that negatively regulates muscle regeneration [48, 49]. Genetic depletion or postnatal pharmacological inhibition of myostatin can lead to increased muscle growth [50, 51]. This phenomenon, which was first observed in mice, was confirmed in multiple species including humans, specifically in a hypermuscular child with a homozygous myostatin mutation whose Olympic sprinter mother also presented with a heterozygous myostatin mutation. Muscle growth has been observed with various pharmacological inhibitors of myostatin in healthy human subjects [51]. Blockade of myostatin results in faster regeneration of skeletal muscle and reduced fibrosis in mouse models of acute and chronic muscle injury [52]. Additionally, the Wagner lab has worked extensively with ActRIIB-Fc, a soluble form of activin receptor IIB conjugated to an Fc immunoglobulin domain, which binds free

myostatin and other activin proteins. ActRIIB-Fc not only enhances myoblast proliferation and differentiation, but also inhibits fibroblast proliferation and collagen production [53]. Fibrosis of muscle is counterproductive to muscle regeneration and can be partially reversed by treatment with ActRIIB-Fc [54].

Despite these promising pre-clinical results with ActRIIB-Fc, clinical trials evaluating the systemic delivery of similar soluble activin receptors were terminated due to unacceptable side effects which were determined to be off-target effects of the drug [55]. However, several other myostatin inhibitors have reached clinical stages and two are currently undergoing Phase 2 clinical evaluation for the treatment of DMD [20]. One of these compounds is a humanized [56] version of RK35, a highly potent and specific monoclonal neutralizing antibody against myostatin [57]. Although the effects of myostatin and its inhibition on skeletal muscle hypertrophy and fibrosis have been extensively characterized, relatively little is known about how these factors affect the immune microenvironment in skeletal muscle.

## **Skeletal Muscle and the Immune System**

The complex cellular and signaling machinery of the immune system has, in addition to maintaining host defense against pathogens, been shown to play a significant role in the repair and regeneration of skeletal muscle [58]. Macrophages, which can adopt a variety of phenotypes, can exert numerous effects on skeletal muscle [59]. M1 macrophages, which infiltrate immediately following neutrophils in the earliest stages of muscle repair,

secrete IGF-1 which promotes the proliferation of local muscle progenitor cells [60]. Pro-inflammatory cytokines upregulated during this phase not only perpetuate local inflammation, but also directly influence myogenesis. IFN- $\gamma$  signaling upregulates the class II transactivator CIITA, which directly binds and inhibits myogenin [61] and other myogenic factors [62]. TNF signaling upregulates the histone methyltransferase EZH2, leading to epigenetic silencing of Pax7 [63] and Notch1 [64].

Switching from the generally proinflammatory M1 phenotype to the generally proregenerative M2 phenotype is closely associated with downregulation of the cell surface marker CD86. This phenomenon is notably mediated by IL-10 released from Foxp3<sup>+</sup> regulatory T cells [65]. The transition to the M2 phenotype eventually leads to the induction of IL-4 signaling and expression of the cell surface markers Fizz1 CD206 [59]. M2 macrophages also facilitate phagocytosis and clearance of dead muscle fibers and other apoptotic cells such as neutrophils, Inhibiting the pro-inflammatory TNF and promoting TGF- $\beta$ , which is key to secretion of ECM required for long-term repair [66, 67]. Additionally at this stage, one group demonstrated that local eosinophils secrete IL-33, potentially signaling local fibro-adipo progenitor cells (FAPs) to adopt a phenotype that promotes debris clearance and repair in cardiotoxin-injured mice, while also inhibiting their fatty, degenerative phenotype [68]. In conditions of chronic injury or disease these mechanisms can go awry, leading to pathological inflammation and fibrosis that can impede normal myogenesis [58]. This lends credence to the concept of targeting the immune system to resolve pathogenic inflammation in DMD [69].

## **Biomaterials and Regenerative Medicine in Skeletal Muscle**

To promote skeletal muscle regeneration, recent advances in the fields of tissue engineering and regenerative medicine have greatly expanded the use of biomaterial scaffolds in a number of applications ranging from volumetric repair and delivery of cells and growth factors to skeletal muscle [70, 71] to 3D-printed artificial muscle constructs [72]. Encouraging results have been reported using small intestinal submucosal scaffolds with endothelial cells, murine myoblasts and foreskin fibroblasts [73], and an injectable polyethylene glycol-fibrinogen hydrogel with human mesoangioblasts [74, 75]. One group has utilized hydrogels to deliver VEGF and IGF-1 in a model of ischemia [6].

Several studies have been reported using decellularized skeletal muscle extracellular matrix, created by removing cellular and nuclear material while retaining pro-regenerative growth factors. This material has been utilized in numerous applications including skeletal [76] and cardiac muscle [77], and has been used to treat volumetric muscle loss [78]. Notably, the field of biomaterials-mediated regenerative immunology has characterized the role of these materials in modulating the immune system to induce pro-regenerative outcomes [79], including the use of extracellular matrix scaffolds to promote CD206 macrophage polarization [80] and type 2 immune signaling [81], facilitating myogenesis. These biomaterials could potentially be utilized towards the development of injectable hydrogels [82] that have the capability to deliver growth factors [70] and create a pro-regenerative immune microenvironment that can be characterized to determine the effects of the material on surrounding tissue [83].

## Overall Summary

Here we utilize an injectable biomaterial composed of hyaluronic acid (HA), a glycosaminoglycan upregulated during muscle hypertrophy [84], and decellularized porcine skeletal muscle extracellular matrix, which has demonstrated considerable utility in previous regenerative medicine applications [78]. HA is conjugated to *N*-hydroxysuccinimide [85], allowing it to readily form a cytocompatible hydrogel at physiological temperatures *in vitro*. The hydrogel is injectable and biodegradable, and promotes the delivery of myostatin inhibitors [57] *in vivo*.

Additionally, injection of hydrogel is associated with a shift in macrophage polarization away from CD86 and towards CD206 expression in both wild type and dystrophic mice, as well as the elevated expression of anti-inflammatory cytokines. When combined with a neutralizing antibody against myostatin, the hydrogel synergistically promotes the induction of regulatory T cells in the local immune microenvironment, revealing potentially novel insights into the interplay between the immune system, myostatin inhibition, and the host response to biomaterials. Finally, the hydrogel also promotes the viability and myogenic capacity of transplanted hESC derived skeletal muscle myoblasts [86], leading to some observed restoration of the dystrophin protein in dystrophic mice. By utilizing biomaterials to create a pro-regenerative environment, this study represents a novel approach to the treatment of Duchenne Muscular Dystrophy.

## **Chapter 2: Fabrication and Characterization of Skeletal Muscle Hydrogel**

## Abstract

A number of biomaterials have been developed for tissue engineering and regenerative medicine in various applications, ranging from bone and cartilage to skeletal muscle. Here we describe the preparation of an injectable biomaterial, known as a hydrogel, utilized throughout this study. The hydrogel consists of hyaluronic acid (HA) conjugated to *N*-hydroxysuccinimide (NHS), and decellularized skeletal muscle extracellular matrix (dSKM-ECM). These materials were combined to form a cytocompatible hydrogel *in vitro*, and determined to be injectable and biodegradable *in vivo*. Additionally, the hydrogel promoted the controlled release of myostatin inhibitors *in vitro*, and increased their bioactivity *in vivo*. **Chapter 2** outlines the fabrication and characterization of an injectable, multifunctional biomaterial with potential regenerative applications in skeletal muscle.

## Introduction

Hydrogels, defined as networks of “water-insoluble crosslinked hydrophilic polymers” [82], have been adopted by the field of tissue engineering for several applications in skeletal muscle, ranging from culturing muscle progenitor cells [87] to growth factor delivery [88] and cell delivery [74, 89, 90]. A number of materials can be used to create hydrogels, including hyaluronic acid, a glycosaminoglycan upregulated during skeletal muscle hypertrophy [84] that has been used as a hydrogel in cardiac tissue applications to deliver cardiomyocytes [85], as well as decellularized extracellular matrix, which has been used alone to form hydrogels that repair cardiac [91] and skeletal [92] muscle.

Although myostatin inhibitors have demonstrated efficacy in ameliorating symptoms in an animal model of DMD [48], systemic administration of one soluble activin receptor during clinical trials led to telangiectasia and epistaxis, leading to termination of the trial [55]. In order to promote site-specific myostatin inhibition in conjunction with the longer-term goal of creating a microenvironment to promote muscle regeneration, we developed a hyaluronic acid / extracellular matrix hydrogel designed to be injectable, cytocompatible *in vitro*, and biocompatible *in vivo*. Functionality of the hydrogel as a drug delivery vehicle was tested utilizing RK35, a potent anti-myostatin antibody [57], as a candidate compound.

## Materials and Methods

### *HA-NHS Synthesis*

Hyaluronic acid functionalization with NHS (HA-NHS) was performed as described previously [85]. Briefly, 10% (w/v) sodium hyaluronate (MW 13-16 kDa, LifeCore Biomedical) was reacted with 67% N-(3-Dimethylaminopropyl)-N'-ethylcarbodiimide (EDC, Sigma) and N-hydroxysuccinimide (NHS, Sigma) in phosphate buffered saline (Gibco) at 37°C for 10 minutes. The resulting mixture was then frozen at -80°C for 1 hour, then precipitated using 100% ethanol pre-cooled to -20°C. Precipitate was centrifuged, washed with -20°C 100% ethanol 9 times, then dried under high vacuum overnight. Functionalization was confirmed by hydroxamate assay [93].

### *Skeletal Muscle ECM Processing*

Skeletal muscle extracellular matrix (M-ECM) was prepared in the same manner as previously described [81]. Yorkshire porcine hindlimb skeletal muscle (Wagner Meats) was trimmed of fat and connective tissue, minced using a knife mill (Retsch) into pieces no larger than 5 mm, then rinsed with distilled water to remove blood and loose particulates. The tissue was then incubated with 3% peracetic acid (Sigma) for 1 hour under constant agitation, followed by replacement with fresh acid solution and an additional 3 hours of agitation at 37°C. Sample was re-equilibrated to neutral pH with several rinses of distilled water and verified with pH indicator strips (Macherey-Nagel), then transferred to 1% Triton X-100 (Sigma) + 2 mM sodium EDTA (Sigma) solution on a room temperature stir plate at 400 rpm for 3 days, changing the solution daily. The

sample was rinsed with distilled water until no bubbles formed from agitation, indicating complete removal of the Triton/EDTA solution, then transferred to 600 units/mL DNase I (Roche) + 10 mM magnesium chloride (J.T. Baker) + 10% Antifungal-Antimycotic (Gibco) for 1 day. Tissues were rinsed with distilled water, frozen at -80°C overnight, then lyophilized for three days. A sample of the resulting dried particulate was fixed in formalin, embedded with paraffin, and sections were taken and stained with Hematoxylin and Eosin (Sigma) to verify proper decellularization. The remaining particulate was pulverized into a powder with a SPEX SamplePrep Freezer/Mill (SPEX CertiPrep) and stored at -20°C prior to use. Phenol chloroform extraction was used to isolate DNA and confirm endogenous DNA degradation using gel electrophoresis.

#### *Rheological Testing*

An ARES G2 Rheometer (TA Instruments) with a solvent trap plate, Peltier solvent trap, and evaporation blocker were used in the mechanical characterization of the material. All tests were performed at 37°C. Gelation testing was performed on 1 mL samples of freshly prepared HA-NHS (15 mg/mL), M-ECM (45 mg/mL), or 6% HA-NHS:M-ECM 1:3 hydrogel. Gelation test parameters were determined as described previously [94] with frequency at 2.0 Hz and oscillation strain at 5.0%; storage and loss moduli were observed over the course of 250 minutes. Data were analyzed via ordinary one-way ANOVA using Tukey's multiple comparisons test in Prism (Graphpad).

### *In vitro Cytocompatibility Assay*

In order to evaluate the cytocompatibility of the hydrogel,  $0.5 \times 10^6$  LHCN-LUC7 immortalized human myoblasts [95] were combined with 45 mg/mL M-ECM in sterile phosphate-buffered saline (PBS), then combined with 15 mg/mL HA-NHS in sterile PBS, yielding a final concentration of  $0.5 \times 10^6$  cells / 1 mL 6% w/v HA-NHS:M-ECM 1:3 hydrogel. Cell-laden hydrogels were added to the wells of a 24-well plate, incubated at 37°C for 50 minutes, then covered with 1 mL human myoblast medium (Medium 199:DMEM 4:1 + 50% fetal bovine serum + 2% penicillin / streptomycin + 0.02 M HEPES + 0.03 µg/mL ZnSO<sub>4</sub> + 1.4 µg/mL Vitamin B12 + 0.055 µg/mL Dexamethasone + 2.5 ng/mL HGF + 10 ng/mL bFGF). Cells were allowed to grow for four days, and then viability was determined using a Live/DEAD Assay Kit (Thermo Fisher). 2 sets of live and dead 10x channel images from n=4 100 µL gels were taken with an EVOS FL microscope (Thermo Fisher), live and dead cells present in each field were counted. Counts were used to calculate the percentage of live and dead cells, which were compared with a two-way ANOVA using Sidak's multiple comparisons test in Prism (Graphpad).

### *In vivo Degradation Assay*

6-week old female wild-type C57BL/6 mice (Jackson Laboratories) were anesthetized under constant isoflurane and their hind limbs were shaved. Each limb was restrained and a 1 cm incision was made above the tibialis anterior muscle to expose the fascia. 50 µL 6% HA-NHS:M-ECM 1:3 hydrogel was injected into the subfascial space of the tibialis anterior with a 1 mL tuberculin syringe (BD) fitted with a 22G needle (Exel). Both legs

were injected for each mouse, and wounds were closed with surgical staples (Roboz). n=2 mice were harvested at 7, 14, and 21 days post-injection, flash frozen with chilled isopentane, serially cryosectioned, stained with Hematoxylin and Eosin, and visualized with an Axio Imager.M2 microscope (Zeiss). 10x H&E images with 10% overlap were taken across the entire section and stitched with Image Composite Editor (Microsoft).

#### *Myostatin Inhibitor In Vitro Release Kinetics*

6% w/v HA-NHA:M-ECM 1:3 hydrogels loaded with 66.67 ng RK35 [56, 57] (Pfizer) were added to a 48-well plate (Corning), allowed to gellate at 37°C for 30 minutes, then 500  $\mu$ L collection medium (McCoy's 5A + 0.1% bovine serum albumin) was added to each well. Collection medium was harvested at 1, 3, and 5 days post-encapsulation, combined with recombinant myostatin (R&D Systems) at 10 ng/mL, then incubated at 37°C for 30 minutes. Each sample was analyzed via luminescence-based assay to measure myostatin bioactivity [96] on a Luminoskan Ascent luminometer (Fisher Scientific) and compared to a standard dilution curve of RK35 + myostatin to calculate the amount of RK35 present, which was then used to calculate % RK35 released. N=3 gels were harvested per timepoint, and n=3 technical replicates were analyzed per sample.

#### *Myostatin Inhibitor In Vivo Bioactivity*

In order to verify the validity of saline vs. hydrogel controls, 4 month old dystrophic male *mdx*-5<sup>Cv</sup> mice (Jackson Laboratories) were injected with 50  $\mu$ L PBS or 50  $\mu$ L 6% w/v HA-NHS:M-ECM 1:3 hydrogel into the subfascial space of the left TA. Each contralateral

limb was used as an internal negative control. 5 days after injection all TAs were weighed and compared via student's T test in Prism (Graphpad). In order to assess myostatin inhibitor activity, 2 month old dystrophic male *mdx*-5<sup>Cv</sup> mice (Jackson Laboratories) were injected with 50  $\mu$ L PBS, 50  $\mu$ L PBS + 10.75  $\mu$ g RK35, or 50  $\mu$ L 6% w/v HA-NHS:M-ECM 1:3 hydrogel + 10.75  $\mu$ g RK35 (n=5 per group) into the subfascial space of the left TA muscle. Each contralateral limb was used as an internal negative control.

5 days after injection all TAs were weighed and compared via one-way ANOVA with Tukey's multiple comparisons test in Prism (Graphpad). RK35-injected TA muscles were flash frozen in chilled isopentane and cryosectioned. Two 7  $\mu$ m sections from regions at least 300  $\mu$ m apart were analyzed from each muscle. Slides were fixed in cold methanol, blocked with 20% normal goat serum in 2% bovine serum albumin (BSA), then incubated overnight with primary antibody against embryonic myosin (DSHB F1.652-s, mouse IgG1 anti-MYH3). Primary antibody was removed, then slides were incubated with Goat Anti-Mouse Alexa Fluor 647 (Thermo Fisher) secondary antibody at 1:500 in 20% NGS + 2% BSA for 1 hour at room temperature. Slides were rinsed in PBS, mounted in Vectashield + DAPI (Vector), and 20x immunofluorescence mosaics were taken with an Axio Imager.M2 microscope (Zeiss). Images were analyzed in ImageJ to determine overall cross-sectional area and embryonic myosin heavy chain signal in terms of integrated density. Slides stained without primary antibodies were used as a negative control, and the strongest eMHC signal field from one hydrogel+RK35 injected muscle was used as a positive control to set exposure constant at 13 ms.

## Results

### *Hydrogel synthesis and characterization.*

Hyaluronic acid was combined with *N*-hydroxysuccinimide (NHS) and reacted with carbodiimide, creating HA-NHS via formation of sulfo-NHS-esters from locally available carboxylic acid groups (**Figure 2.1A**). A hydroxamate assay was performed to verify conjugation, revealing that 22.41% of the carboxylic acid groups present on HA formed sulfo-NHS-esters (data not shown). Porcine skeletal muscle tissue was separated from fatty and connective tissue, rinsed, minced, and subjected to a standard processing protocol [81] to yield decellularized skeletal muscle extracellular matrix (M-ECM) (**Figure 2.1B**). Decellularization was verified by extracting DNA from the processed ECM sample and comparing it to a standard DNA ladder, revealing that only small fragments of nuclear material remained (**Figure 2.1C**). Further characterization was performed by histological assessment of the processed ECM material, which revealed a lack of visibly apparent cellular and nuclear material after staining for hematoxylin and eosin (**Figure 2.1C**). 30 mg/mL HA-NHS and 90 mg/mL M-ECM were combined to yield a final 6% w/v HA-NHS:M-ECM 1:3 (HA-ECM) composite which formed a hydrogel at physiological temperatures *in vitro*. Time sweep rheology [94] revealed a steady increase and eventual plateau of the hydrogel storage modulus not observed with either component alone (**Figure 2.2**).

#### *Hydrogel cytocompatibility and biocompatibility.*

In order to assess cytocompatibility, immortalized human myoblasts [95] were combined with the hydrogel and seeded *in vitro*. Cell viability was assessed at 4 days post-encapsulation via Live/DEAD visualization of two fields in four gels (**Figure 2.3A, Supplementary Figure 2.1**), and almost no dead cells were observed (**Figure 2.3B**). The hydrogel was injected into the subfascial space above the tibialis anterior (TA) muscles of wild-type C57BL/6 mice in order to assess its biocompatibility *in vivo*. Labeling the hydrogel with blue dye allowed for visualization of the hydrogel spreading across the entire intertendinous space of the TA when injected subfascially (**Figure 2.4A**). Harvest and histological evaluation of hydrogel-injected muscles revealed that the hydrogel degrades over the course of 21 days *in vivo* with no long-standing myotoxic effects (**Figure 2.4B**).

#### *Hydrogel-mediated delivery of cells and myostatin inhibitors in vivo.*

Since biomaterials have demonstrated several applications in skeletal muscle, we assessed the multifunctionality of the hydrogel by determining its ability to deliver growth factors *in vivo*. Growth factor delivery was assessed with hydrogels containing the anti-myostatin antibody RK35 [57] both *in vitro* and *in vivo* (**Figure 2.5**). A luminescence-based assay [96] was used to generate a standard curve of myostatin inhibition (**Supplementary Figure 2.2**), which was then used to quantify the amount of RK35 present in supernatant samples taken from RK35-laden hydrogels *in vitro*, allowing for determination of the percentage of RK35 release over time. Controlled release of

RK35 from the hydrogel was observed over the course of five days, peaking at 20% release of the encapsulated compound (**Figure 2.5A**). *Mdx-5<sup>Cv</sup>* mice, which serve as a model of Duchenne Muscular Dystrophy [97], were used to evaluate RK35 bioactivity when delivered to uninjured TA muscles via saline or hydrogel *in vivo* (**Figure 2.5B-D, Supplementary Figures 2.3-2.4**). Saline-injected muscles were demonstrated to have similar weights to hydrogel-injected muscles, and thus were deemed appropriate as a treatment-free control (**Supplementary Figure 2.3**). RK35-hydrogel injected muscles showed greater weight and overall cross-sectional area compared to muscles injected with RK35 in saline (**Figure 2.5 B-C**). Immunofluorescence labeling of embryonic myosin heavy chain (eMHC), a marker of regeneration, revealed greater eMHC signal density in muscles injected with RK35 and hydrogel compared to saline (**Figure 2.5D, Supplementary Figure 2.4**).

## Discussion

Given the previously demonstrated utility of biomaterial hydrogels in regenerative medicine applications [82] and drug delivery [98], we sought to apply these principles to the treatment of DMD. Here, we have utilized the techniques of carbodiimide chemistry and tissue decellularization to create a hyaluronic acid / ECM composite hydrogel. The gel was demonstrated to be cytocompatible with immortalized human skeletal muscle myoblasts (**Figure 2.3**), injectable (**Figure 2.4A**), and biocompatible (**Figure 2.4B**). Additionally, the hydrogel facilitated the controlled release of the myostatin inhibitor RK35 *in vitro* (**Figure 2.5A**) and promoted its bioactivity *in vivo* (**Figure 2.5B**).

Some limitations do arise in the preparation of each of the hydrogel component materials. Even though only 22.41% of the available carboxyl groups present on the hyaluronic acid backbone were reacted, this is in line with previous results describing this chemical conjugation to chondroitin sulfate [93] and actually exceeds the 16.67% conjugation previously observed with hyaluronic acid [85]. Despite extensive processing of porcine-derived skeletal muscle, some nuclear material remained (**Figure 2.1C**). Although it may not be possible to remove all exogenous nuclear material, the standard DNase I treatment is sufficient to remove large fragments, leaving only small traces of nuclear material that are relatively non-immunogenic.

Rheology (**Figure 2.2**) revealed that gelation of the material composite takes a relatively long time *in vitro*, and the low terminal storage modulus indicates that this is a relatively weak gel. Skeletal muscle itself adopts an elastic modulus of 13-18 kPa [70], roughly two orders of magnitude stronger than this material, which exhibited a peak storage modulus of approximately 30 Pa. However, the primary design factor of the hydrogel was not necessarily structural repair but implantation, creating a material that modulates the local environment to support the effective regeneration *in vivo*, complemented by localized delivery of the myostatin inhibitor. The fact that HA-NHS and decellularized skeletal muscle ECM were unable to individually exhibit gelation properties similar to that of the composite material demonstrates that some crosslinking does occur between conjugated *N*-hydroxysuccinimide groups on the HA backbone and locally available primary amines in the ECM.

The increased viscosity of this material, as well as the opportunity for NHS groups to react with primary amines in local tissue, facilitates the retention of the hydrogel *in situ*, potentially contributing to the increased bioactivity of the myostatin inhibitor RK35 *in vivo* (**Figure 2.5 B-D**). Because the hydrogel itself does not swell appreciably (**Figure 2.2**), nor does it significantly contribute to the weight of injected muscles *in vivo* (**Supplementary Figure 2.3**), the observed increase in muscle weights and overall cross-sectional areas was most likely due to the hypertrophic effects of myostatin inhibition associated with RK35 (**Figure 2.5B-C**). This was confirmed upon observation of the increased staining density of embryonic myosin heavy chain (**Figure 2.5D**).

RK35 is a highly specific, direct inhibitor of myostatin [56, 57], contrasted with ActRIIB-Fc, a soluble activin receptor decoy which despite positive results *in vitro* has been previously tested and retracted from clinical trials due to side effects [55], presumably from off target effects on other activin signaling pathways. Although RK35 already has higher potency, specificity, and half-life compared to soluble activin receptors [56], targeted specific delivery to muscles most severely affected by DMD could still confer a number of benefits: further reduction of off-target effects, decreased overall concentrations of drug used to treat patients, and, in concert with the presence of pro-myogenic growth factors in the locally crosslinked decellularized skeletal muscle extracellular matrix, the creation of a pro-myogenic microenvironment that could have direct effects on any muscle progenitor cells transplanted with this hydrogel.

Gel 3:

Gel 4:

**Supplementary Figure 2.1. Representative images used to determine cell viability in hydrogel.**  $0.5 \times 10^6$  LHCN-LUC7 immortalized human myoblasts were seeded into hydrogels *in vitro* and assessed for cytocompatibility after 4 days. Fluorescence images of live (green) and dead (red) immortalized human myoblasts at 4 days post-hydrogel encapsulation *in vitro*. 2 live and dead fields were imaged from N=4 gels. All images taken at 10x.

**Supplementary Figure 2.2. TA204 + myostatin response curve.** Serum-starved TA204 cells were treated with several concentrations of myostatin (160-0 ng/mL, top panel) or with 10 ng/mL myostatin and various concentrations of RK35 (0-10 nM, bottom panel). Response levels were determined by differential emission of luciferase. N=3 technical replicates per data point.

**Supplementary Figure 2.3. Saline and hydrogel-injected TAs used to verify controls.**

N=5 TAs were injected with 50  $\mu$ L PBS or hydrogel, harvested at 5 days post-injection, and weighed. TA weights were compared via student's T test in Prism (Graphpad).

## **Chapter 3: Hydrogel-Mediated Effects on the Immune Microenvironment**

## Abstract

Several studies have implicated the immune system as a significant mediator of skeletal muscle repair and regeneration, and extracellular matrix-based biomaterials have been shown to play a role in polarizing the immune microenvironment towards pro-myogenic outcomes. However, the study of the immune response to biomaterials has not been evaluated within the context of DMD. Towards this end, we have utilized a previously established method to characterize the overall immunological response to the HA-ECM hydrogel described in **Chapter 2**. The hydrogel promotes the infiltration of scaffold-associated macrophages and expression of anti-inflammatory cytokines in both wild type and dystrophic mice. Notably, combining the hydrogel and myostatin inhibitor Rk35 affects T cell polarization, and yields a substantial increase in Foxp3<sup>+</sup> regulatory T cells - an effect not observed with any individual component of the hydrogel or RK35 alone **Chapter 3** outlines the analysis of immune cell populations present around (and possibly influenced by the presence of) the hydrogel scaffold, known as the scaffold immune microenvironment, as well as the effects of the hydrogel on proximal systemic cytokine expression *in vivo*.

## Introduction

A number of recent studies [58] have explored the complex interplay between the processes of skeletal muscle repair and activation of the immune system, particularly within the context of DMD [69]. The population of immune cells and soluble factors such as cytokines form a distinct immune microenvironment that has direct effects on the process of myogenesis, ranging from effects on satellite cell proliferation and differentiation to normal versus pathological induction of fibrosis. This has been further studied within the context of the response to biomaterials in skeletal muscle. Previous work has demonstrated the presence of M2-like CD206<sup>+</sup> scaffold-associated macrophages [83] modulated by biomaterials in skeletal muscle that work with type 2 signaling through IL-4 and CD4<sup>+</sup> T-cells to promote regeneration [81].

Despite these advances, the immunological response to biomaterials has not been evaluated within the context of DMD, and the effects of myostatin inhibition on the dystrophic immune microenvironment are still unknown. Here, we evaluated the effects of the hydrogel described in **Chapter 2**, its individual components, and myostatin inhibitors on the immune microenvironment in wild type and dystrophic *mdx* mice. We used immunofluorescence and flow cytometry to characterize modulated cell populations, and qPCR to evaluate cytokine expression in local draining lymph nodes proximal to the injected biomaterial. Overall, we observed polarization towards a pro-regenerative immune microenvironment in the presence of the hydrogel and myostatin inhibitor in *mdx* mice.

## Materials and Methods

### *Materials Implantation*

1 month old female WT C57BL/6 and dystrophic mdx-5<sup>Cv</sup> mice (Jackson Laboratories) were bilaterally injected with 50  $\mu$ L PBS or 6% w/v HA-NHS:M-ECM 1:3 hydrogel. 2-5 month old male dystrophic mdx-5<sup>Cv</sup> mice (Jackson Laboratories) were bilaterally injected with 50  $\mu$ L PBS, 30 mg/mL HA-NHS, 90 mg/mL M-ECM, 6% w/v HA-NHS:M-ECM 1:3 hydrogel, PBS + 10.75  $\mu$ g RK35, or 6% w/v HA-NHS:M-ECM 1:3 hydrogel + 10.75  $\mu$ g RK35. In all cases, mice were anesthetized with isoflurane and shaved prior to injection. Each limb was restrained and a 1 cm cutaneous incision was made above the tibialis anterior muscle to expose the fascia. All materials were injected into the subfascial space of the tibialis anterior (TA) muscle with a 1 mL tuberculin syringe (BD) fitted with a 22G needle (Exel). Both legs were injected for each mouse, and wounds were closed with surgical staples (Roboz). All animals were sacrificed at 1 week post-injection.

### *Proximal Lymph Node Cytokine Analysis*

Upon harvest, inguinal lymph node pairs (n=4) were visually identified, isolated from each animal, and frozen. Lymph node pairs were then minced and homogenized in Trizol (Invitrogen). RNA was extracted from each sample with chloroform, and then isolated using an RNEasy Extraction Kit (Qiagen). RNA concentration for each sample was determined with a Nanodrop 2000 spectrophotometer (Thermo Scientific), and 1  $\mu$ g RNA was used to produce cDNA using an iScript cDNA Synthesis Kit (Bio-Rad). qPCR was performed with PowerUP SYBR (Thermo Fisher) on a CFX Connect (Bio-Rad) with

primers diluted to 20  $\mu$ m (**Table 3.1**). Data were analyzed as calibrated normalized relative quantities (CNRQ) over saline group for each genotype, and statistically compared via one-way ANOVA with Tukey's multiple comparisons test in qBase+ (Biogazelle). Graphs were rendered in Prism (Graphpad).

### *Immune Characterization*

Upon harvest, both tibialis anterior (TA) muscles were harvested from each animal. N=4 animals from each group were used for FACS analysis, and n=1 spleen was processed and split for use in unstained, viability, single-color, and full-panel control samples. Samples were minced, then digested with Liberase TL (Roche) for 45 minutes or Liberase TM (Roche) with DNase I (Roche) in RPMI-1640 medium (Gibco) for 30 minutes under constant agitation at 37°C. The resulting single-cell suspensions were filtered through a 100 micron filter (Fisher Scientific) and counted with a Countess II FL (Thermo Fisher) (**Supplementary Table 3.1**). All samples were treated with ACK lysing buffer (Quality Biological), subjected to cytokine stimulation, stained with FACS antibodies (BioLegend, Thermo Fisher, or BD) and viability dye (eBiosciences) (**Table 3.2-3.3**), fixed in Cytofix (BD), and analyzed with an LSR II or Fortessa (BD). Data were analyzed and gated (**Supplementary Figures 3.1, 3.4**) in FloJo (Treestar) or Diva (BD), population percentages were calculated in terms of %CD45<sup>+</sup> cells, then normalized to cell counts to yield absolute cell numbers. Overall mean fluorescence intensity (MFI) was also calculated for the fluorescent channels corresponding to CD86 and CD206 in each experiment as another overall determinant of macrophage polarization.

### *Immunohistochemistry*

Upon harvest, both tibialis anterior (TA) muscles were harvested from n=1 animal from each group. Each TA was flash frozen in chilled isopentane and cryosectioned. Six 7  $\mu$ m sections were stained per muscle from regions spread at least 150  $\mu$ m apart.

Immunofluorescence slides were fixed in cold methanol for 10 minutes, rinsed with PBS for 5 minutes, blocked with 20% normal goat serum (NGS) in 2% bovine serum albumin (BSA), then incubated with primary antibodies against F4/80 (BioLegend BM8, Rat IgG2a anti-mouse F4/80) and Fizz1 (Peprotech 500-P215, Rabbit Polyclonal anti-Mouse RELM $\beta$ ) at 1:500 20% NGS + 2% BSA at 4°C overnight. Primary antibody was removed from sections, then incubated with Goat Anti-Rat Alexa Fluor 488 and Goat Anti-Mouse Alexa Fluor 647 secondary antibodies (Thermo Fisher) at 1:500 in 20% NGS + 2% BSA for 1 hour at room temperature. Slides were rinsed in PBS and mounted in Vectashield + DAPI (Vector). 20x immunofluorescence mosaics and 40x oil objective single extended focus images were taken with an Axio Imager.M2 microscope and rendered in Axiovision (Zeiss).

## Results

### *Immunomodulatory effects of hydrogel in wild type and dystrophic mice.*

Potential immunomodulatory effects of the hydrogel were tested in comparison to saline in both wild-type C57BL/6 and dystrophic *mdx-5<sup>Cv</sup>* mice. Cryosections of injected TA muscles revealed the presence of F4/80<sup>+</sup>Fizz1<sup>+</sup> macrophages in hydrogel-injected muscles, but not saline (**Figure 3.1**). Single-cell suspensions were obtained from each muscle and analyzed by FACS (**Supplementary Figure 3.1**). Macrophages (CD45<sup>+</sup>CD11b<sup>+</sup>F4/80<sup>+</sup>MHCII<sup>+</sup>) were prominent in all hydrogel-injected conditions (**Figure 3.2**) with significantly more CD206<sup>+</sup> macrophages found in hydrogel-injected wild type and dystrophic mice (**Figure 3.2C**). CD86<sup>+</sup>CD206<sup>+</sup> macrophages were most prominent in saline-injected dystrophic mice. Analysis of mean fluorescence intensity (MFI) (**Supplementary Figure 3.3**) indicated reductions in CD86-associated fluorophore signal in hydrogel-injected mice compared to saline, which was significant in dystrophic mice. No significant differences were observed in CD206-associated fluorophore MFI between groups, but corresponding decreases in CD86-fluorophore signal indicate an overall polarization away from CD86 and towards CD206 in hydrogel-injected mice. Inguinal lymph nodes, which are most proximal to injected muscles, showed significantly elevated expression of IL-4 in hydrogel-injected mice of both genotypes, but differences in IL-10 expression were only observed in wild-type mice (**Figure 3.3**).

### *Effects of hydrogel and myostatin inhibitor on macrophage populations.*

In addition to the HA-ECM hydrogel, each of its individual components (HA-NHS, M-

ECM) was injected into aged *mdx*-5<sup>Cv</sup> mice to evaluate their immunomodulatory properties. Since the hydrogel demonstrated the ability to deliver RK35 *in vivo* (**Figure 2.5**), additional mice were injected with RK35 in saline and hydrogel.

Immunofluorescence revealed F4/80<sup>+</sup>Fizz1<sup>+</sup> macrophages in ECM, hydrogel, and hydrogel + RK35 mice (**Figure 3.4**). Cytometric analysis (**Figure 3.5**) revealed significantly reduced numbers of CD11b<sup>+</sup> cells in M-ECM and RK35 injected mice. (**Supplementary Figure 3.5**), and significantly greater percentages of CD86<sup>+</sup> (M1) and CD86<sup>+</sup>CD206<sup>+</sup> macrophages in mice injected with HA-NHS. Hydrogel injected mice exhibited significantly more CD206<sup>+</sup> macrophages; co-delivery of RK35 with the hydrogel also induced the CD86<sup>+</sup>CD206<sup>+</sup> population. MFI analysis revealed a shift in macrophage polarization towards CD86 in HA-NHS treated mice (**Supplementary Figure 3.3**).

*Effects of hydrogel and myostatin inhibitor on T cell populations and cytokine signaling.*

Mice injected with hydrogel + RK35 exhibited elevated levels of CD3<sup>+</sup> T cells compared to all other groups (**Supplementary Figure 3.5**). FACS revealed significantly greater numbers of CD4<sup>+</sup> cells (**Figure 3.6A**) and Foxp3<sup>+</sup> regulatory T cells (**Figure 3.6B**) in mice injected with both RK35 and hydrogel, more than any other group. Mice injected with hydrogel + RK35 also exhibited elevated levels of IL-17<sup>+</sup> T cells (**Supplementary Figure 3.5**). Inguinal lymph nodes showed elevated expression of IL-4 in ECM, hydrogel, and hydrogel+RK35 injected mice. No substantial differences were detected in IL-10, and a slight TNF- $\alpha$  increase was detected in hydrogel+RK35-injected mice (**Figure 3.7**). No other significant differences were observed in IL-17, IL-6, IL-1 $\beta$ , IFN- $\gamma$ , Arg1, or Retn1 $\alpha$ .

## Discussion

This set of experiments represents the first evaluation of the effects of implanted biomaterials and myostatin inhibition on the skeletal muscle immune microenvironment in DMD. Immunofluorescence images of hydrogel-injected muscles revealed the presence of CD206<sup>+</sup> macrophages (**Figure 3.1, Figure 3.4**), which was further confirmed with flow cytometry (**Figure 3.2, 3.5**). Additionally, mice injected with the hydrogel demonstrated significantly elevated interleukin-4 expression in local draining lymph nodes (**Figure 3.3, 3.6**). Finally, analysis of CD3<sup>+</sup> T cell populations via flow cytometry revealed significantly elevated numbers of CD3<sup>+</sup> T cells, CD3<sup>+</sup>CD4<sup>+</sup> T helper cells, CD3<sup>+</sup>CD4<sup>+</sup>Foxp3<sup>+</sup> regulatory T cells, and IL-17<sup>+</sup> secreting T cells in mice injected with the myostatin inhibitor RK35 delivered via hydrogel (**Figure 3.5, Supplementary Figure 3.5**).

The modulation of M2-like CD11b<sup>+</sup>F4/80<sup>+</sup>CD11c<sup>±</sup>CD206<sup>hi</sup>CD86<sup>+</sup>MHCII<sup>+</sup> scaffold-associated macrophages by implanted biomaterials has been established previously [83], and their role alongside CD4<sup>+</sup> T cells in promoting regenerative outcomes in biomaterials-implanted mice is also well known [81]. Although there is significant potential for mechanisms of the immune system to go awry within the context of chronic injury or diseases such as DMD [58], macrophage polarization remained intact in dystrophic mice at one week post-injection (**Figure 3.1**). Foxp3<sup>+</sup> regulatory T cells, an immune cell population responsible for mediating overall immune responses and facilitating the transition of macrophages from the M1 to the M2 phenotype in skeletal muscle [58], have been previously targeted for upregulation in dystrophic *mdx* mice via

treatment with IL-2/anti-IL-2 complexes that specifically act on these cells, leading to consequent increases in IL-10, reduced expression of cyclooxygenase-2, and reduction of pathologic muscle inflammation and injury [99]. Here, we observed a substantial upregulation of Foxp3<sup>+</sup> regulatory T cells in mice injected with both hydrogel and the myostatin inhibitor RK35, a phenomenon not observed with RK35, the hydrogel, or any of the individual hydrogel components (**Figure 3.5**). This elevation of the regulatory T cell population was, however, insufficient to significantly increase expression of interleukin 10 in inguinal lymph nodes of dystrophic *mdx* mice (**Figure 3.6**), as observed in comparable wild-type animals (**Figure 3.3**). Nonetheless, this synergistic upregulation observed with both hydrogel and myostatin inhibitor delivered together suggests the existence of a novel immunomodulatory function for this combination. Future studies with co-delivery of hydrogel and RK35 separately administered systemically, intramuscularly, or in other controlled release vehicles such as polymeric fibers or spheres could be used to determine whether this effect is simply due to the presence of RK35 in conjunction with hydrogel, or its localization and/or sustained release.

A great deal of work remains in determining the underlying mechanisms driving the pro-regenerative effect of the hydrogel and myostatin inhibitor. Given the complex temporal kinetics of immune-mediated regulation of muscle [58], characterization of the scaffold immune environment at shorter or longer timepoints may add an additional layer of understanding to the host response to this material. In addition to the extracellular matrix present in the hydrogel, hyaluronic acid also has complex, variable effects on the

immune system through direct interaction with RHAMM and CD44 [100] that may affect local immune responses to the material. Myostatin inhibition has previously been shown to ameliorate TNF- $\alpha$ -mediated rheumatoid arthritis in mice [101], but its effects on muscle immunology are still relatively unknown. Specific isolation and transcriptome characterization of isolated specific immune cell populations present could clarify the signaling mechanisms modulated in response to the hydrogel or RK35.

Additionally, some limitations are also present with the mouse model. Even though *mdx-5<sup>Cv</sup>* mice demonstrates profound defects compared to wild-type mice [97], hindlimb skeletal muscles are not as symptomatically severe as those of DMD patients, or even other muscles within the same animal, such as the diaphragm. Evaluation of these materials in dystrophic mice with or without myostatin inhibitor in more profoundly affected muscles such as the diaphragm, or in conjunction with injuries such as myotoxin, cryogenic, burn, or volumetric injury [102] may further elucidate the underlying mechanisms that shape the immune microenvironment in Duchenne Muscular Dystrophy. Comparative assessment of the hydrogel and myostatin inhibitor under healthy and injured conditions in both wild type and dystrophic mice could also potentially determine the effects of the immune environment and biomaterial on functional regeneration and repair, either through *ex vivo* physiologic assessment of individual muscles or whole-animal studies such as grip strength tests, hanging tests, rota-rod balance assessment, or endurance-based treadmill testing [103].

## **Chapter 4: Hydrogel-Mediated Transplantation of Skeletal Muscle Cells**

## Abstract

Despite decades of development, cellular therapies for the treatment of DMD have remained largely ineffective. Here we describe the *in vivo* characterization of a novel population of human embryonic stem cell derived muscle progenitor cells for use in cell therapy, as well as the application of the injectable biomaterial hydrogel described in **Chapter 2** to increase the effectiveness of their transplantation. Human stem-cell derived myoblasts injected into immunodeficient mice formed human muscle fibers *in vivo* and occupied the local progenitor cell niche, driving long term repair after injury. Transplantation of cells with the hydrogel promoted their viability at short-term timepoints, and a long-term pilot study revealed their capability to restore Dystrophin in immunodeficient dystrophic mice. **Chapter 4** describes the first application of an injectable biomaterial to increase the effectiveness of stem cell transplantation in DMD.

## Introduction

The transplantation of healthy skeletal muscle progenitor cells into dystrophic recipients in order to partially or completely restore Dystrophin expression has been explored and evaluated by numerous groups since the late 1980s [40]. However, even after numerous preclinical and clinical trials, the results of cell therapy in DMD have been largely ineffective [47]. Obtaining sufficient numbers of transplant-competent muscle progenitor cells remains a difficult process, transplanted cell viability tends to be poor, and donor cell engraftment in terms of Dystrophin restoration and functional outcomes has largely been clinically insignificant.

Here, human skeletal muscle progenitor cells derived with a previously described dual-SMAD inhibition strategy [86] were evaluated for their capacity to serve as donor cells to not only form human muscle fibers but also act as the primary driver of skeletal muscle repair after injury. Additionally, the injectable hyaluronic acid – skeletal muscle ECM hydrogel characterized in **Chapter 2** was utilized to promote the effectiveness of muscle myoblast transplantation in short-term and long-term studies. Through direct visualization and semi-quantitative assessment of cell survival and donor-derived myofiber formation, both the hydrogel and human pluripotent stem cell derived myoblasts were evaluated for their applicability towards cell therapy for DMD.

## Materials and Methods

### *Characterization of hESC derived myoblasts*

Human embryonic stem cell derived myoblasts were derived by the Lee Lab as described in Choi et. al. [86], via treatment of hESCs with CHIR99021 for 4 days, followed by DAPT treatment for 8 days, and further maintenance in culture for at least 18 days to allow for differentiation into the myogenic lineage [86]. 2-6 month old male NOD-Rag1<sup>null</sup>-IL2rg<sup>null</sup> (NRG) or NOD-SCID-IL2rg<sup>null</sup> (NSG) mice (Jackson Laboratories) mice were irradiated with 18 Gy in the left or both hindlimbs with either a Shepherd Mark I (JL Shepherd) or a micro-CT guided Small Animal Radiation Research Platform (Xstrahl) [104] in order to ablate the endogenous satellite cell population. After three days, irradiated TAs were injured via injection of 100 µL 10 mM cardiotoxin (*Naja Mossambica*, Sigma) or 50 µL 1.2% BaCl<sub>2</sub> (Sigma) [102]. 24 hours after injury, 1-3 x 10<sup>6</sup> cells were injected into the left TA, with the right leg serving as an uninjected control.

All TA muscles were harvested 4-8 weeks after each injection; serially injured mice received a second TA injury of 50 µL 1.2% BaCl<sub>2</sub> at six weeks post-transplantation and were harvested two weeks later. TA muscles were flash frozen in chilled isopentane and 7 µm cryosections were taken. Slides were fixed in cold methanol and blocked with 20% normal goat serum (NGS) in 2% bovine serum albumin (BSA). Fixed slides were incubated with primary antibodies against human lamin A+C (NCL-LAM-AC, mouse IgG2b, 1:100, Leica), pan-species Pax7 (PAX7, mouse IgG1, 1:1, DSHB), human laminin (2E8, mouse IgG2a, 1:100, DSHB), and human Dystrophin (MANDYS106, mouse IgG2a,

1:100, Leica), and secondary antibodies (goat anti-mouse IgG1 Alexa Fluor 488 1:500, goat anti-mouse IgG2a Alexa Fluor 647 1:500, goat anti-mouse IgG2b Alexa Fluor 555 1:500, Thermo Fisher). Pax7-stained slides underwent tyramide signal amplification (Thermo Fisher). Stained sections were mounted using Vectashield with DAPI (Vector Laboratories), and imaged using confocal (Olympus) or fluorescence microscopy (Zeiss). Comparison of N=2-3 serially injured muscles versus uninjured controls was performed via Mann-Whitney test in Prism (Graphpad).

#### *Short-term transplantation of hydrogel-injected myoblasts*

For semiquantitative analysis, 1 month old male immunodeficient NOD-Rag1<sup>null</sup>-IL2rg<sup>null</sup> (NRG) mice (Jackson Laboratories) were bilaterally injured via intramuscular injection of 100  $\mu$ L 10  $\mu$ M cardiotoxin (Roche) [102] into shaved tibialis anterior (TA) muscles. 24 hours post-injury, 0.5x10<sup>6</sup> LHCN-LUC7 immortalized human myoblasts [95] suspended in 50  $\mu$ L PBS or 6% w/v HA-NHS:M-ECM 1:3 hydrogel were subfascially injected above each TA muscle as described previously. 7 days after injection, muscles were frozen in chilled isopentane, cryosectioned, stained with primary antibodies against human lamin A+C (NCL-LAM-AC, mouse IgG2b, 1:100, Leica) and secondary antibodies (goat anti-mouse IgG2b Alexa Fluor 555 1:500, Thermo Fisher) and imaged using fluorescence microscopy (Zeiss). Human Lamin A+C<sup>+</sup> nuclei present in each section were manually counted in ImageJ. N=6 sections were analyzed per muscle from regions at least 150  $\mu$ m apart and

used to calculate percent cell survival. 4 muscles from n=2 animals were analyzed per group. All parameters were analyzed via two-way ANOVA in Prism (Graphpad).

For cytometric analysis, 1.5 month old male immunodeficient dystrophic NOD-SCID-IL2 $\gamma$ <sup>-</sup>mdx-4<sup>Cv</sup> (NSG-4Cv) mice (University of Minnesota) [105] were irradiated with 18 Gy X-ray radiation with a micro-CT guided Small Animal Radiation Research Platform (Xstrahl) [104], intramuscularly injured with 50  $\mu$ L 1.2% BaCl<sub>2</sub> after 24 hours [102], and transplanted with 1x10<sup>6</sup> human ES-derived GFP<sup>+</sup> muscle progenitor cells (unpublished) in 50  $\mu$ L PBS or hydrogel subfascially above the injured TA muscle (n=5 per group) 24 hours after injury. After 10 days post-transplantation, mice were euthanized, TA muscles were removed, and a single cell suspension was yielded as described previously [106]. Each sample was analyzed using a FACS Calibur + CellQuest Pro (BD), and the relative percentages of transplanted GFP<sup>+</sup> cells were determined for each sample. Sample group means were compared via Mann-Whitney test using Prism (Graphpad).

#### *Long-term transplantation of hydrogel-injected myoblasts*

1-2 month old male immunodeficient dystrophic NOD-SCID-IL2 $\gamma$ <sup>-</sup>mdx-4<sup>Cv</sup> (NSG-4Cv) mice were irradiated with 18 Gy X-ray radiation with a micro-CT guided Small Animal Radiation Research Platform (Xstrahl) [104], intramuscularly injured with 50  $\mu$ L 1.2% BaCl<sub>2</sub> [102] after 24 hours, and transplanted with 1x10<sup>6</sup> hESC derived myoblasts [86] in 50  $\mu$ L PBS or 6% w/v HA-NHS:M-ECM 1:3 hydrogel alone or with 10.75  $\mu$ g RK35 as described previously (n=1 each). After 4 months post-transplantation, mice were

euthanized and TA muscles were removed. Cryosections were obtained and stained with primary antibodies against human lamin A+C (Mouse IgG2b, 1:100, Leica), pan-species Pax7 (IgG1, 1:1, DSHB), pan-species Dystrophin (Rabbit, 1:100, Abcam), human laminin (IgG2a, 1:100, DSHB), and human Dystrophin (IgG2a, 1:100, Leica), and secondary antibodies (goat anti-rabbit Alexa Fluor 488 1:500, goat anti-mouse IgG1 Alexa Fluor 488 1:500, goat anti-mouse IgG2a Alexa Fluor 647 1:500, goat anti-mouse IgG2b Alexa Fluor 555 1:500, Thermo Fisher). Pax7-stained slides were also subjected to tyramide signal amplification (Thermo Fisher). Stained sections were mounted using Vectashield mounting medium with DAPI (Vector Laboratories), and imaged using fluorescence microscopy (Zeiss). Observed human Laminin<sup>+</sup> and human Dystrophin<sup>+</sup> fibers were counted from six 7 µm cryosections from each muscle taken at least 150 µm apart. All groups were compared via one-way ANOVA in Prism (Graphpad).

## Results

### *In vivo characterization of human pluripotent stem cell derived myoblasts.*

Human pluripotent stem cells derived to the myogenic lineage using a dual-SMAD inhibition strategy [86] were transplanted into irradiated, myotoxin injured tibialis anterior (TA) muscles of immunodeficient mice. At 4 weeks post-injection (**Figure 4.1**), viable human nuclei were observed in transplanted TAs as determined by positive staining for the nuclear marker human Lamin A+C. Human skeletal muscle laminin was also observed, consistent with mature myofibers. Some progenitor cells localized within human laminin<sup>+</sup> fibers, occupying the satellite cell niche (**Figure 4.1 inset**).

Niche occupancy of progenitors was further verified by immunofluorescence labeling of transplanted muscles with antibodies against Pax7, a marker of satellite cells. Co-localization of Pax7 with human Lamin A+C, which is only present in donor-derived human nuclei, confirmed the occupancy of donor myoblasts in the satellite cell niche (**Figure 4.1**). Since local satellite cells are the primary mediators of skeletal muscle repair after injury, transplanted muscles were subjected to a secondary myotoxin injury to assess this functionality in donor-derived myoblasts. Analysis of injured transplanted TAs revealed a greater proportion of human Laminin<sup>+</sup> and human Dystrophin<sup>+</sup> fibers than transplanted TA muscles that were injured only once (**Figure 4.2**).

*Effects of hydrogel on short-term transplantation of human muscle progenitor cells.*

The hydrogel described in **Chapter 2** was further explored by determining its ability to deliver cells *in vivo*. 24 hours after cardiotoxin injury, immunodeficient mice were transplanted with immortalized human myoblasts suspended in saline or hydrogel. After 1 week, visual assessment of each muscle revealed twice as many human nuclei in hydrogel-transplanted mice compared to saline-transplanted mice (**Figure 4.3**). This was confirmed with a human pluripotent stem cell-derived myoblast line [86] modified to constitutively expresses GFP. 10 days after transplantation of these cells into irradiated, myotoxin-injured immunodeficient dystrophic mice, single-cell populations analyzed by flow cytometry revealed a significantly greater percentage of donor-derived GFP<sup>+</sup> cells in hydrogel-transplanted muscles when compared to saline (**Figure 4.4**).

*Effects of hydrogel on long-term transplantation of human muscle progenitor cells.*

Four months after irradiation, myotoxin injury, and transplantation of human embryonic stem cell-derived myoblasts into immunodeficient mice, muscles were cryosectioned and the number of human Laminin<sup>+</sup> and Dystrophin<sup>+</sup> fibers was counted. Significantly greater numbers of human Laminin<sup>+</sup> (**Figure 4.5A**) and Dystrophin<sup>+</sup> (**Figure 4.5B**) fibers were observed in hydrogel-transplanted mice compared to saline-transplanted mice. Furthermore, nuclei that co-stained human Lamin A+C<sup>+</sup> and Pax7<sup>+</sup> within human Dystrophin<sup>+</sup> fibers were observed in both conditions, verifying the long-term ability of saline- and hydrogel-transplanted human pluripotent stem cell derived myoblasts to occupy the satellite cell niche.

## Discussion

In this study, increased numbers of donor-derived myoblasts were observed in mice transplanted with hydrogel compared to saline (**Figures 4.3-4.4**). The hydrogel may have conferred a number of positive effects on viability and engraftment through mechanisms established in other studies, including protection from a harsh host environment [49] or reduction of anoikis, programmed cell death that occurs in anchorage-dependent cells that are detached from the extracellular matrix [107]. One key property of the hydrogel that may have also played a role is the dispersion of transplanted cells; without adequate spreading, progenitor cells either localize predominantly around the injection site or adopt a perifascicular pattern of engraftment [108], preventing widespread formation of donor-derived myofibers *in situ*.

The slow but defined gelation pattern established with the hydrogel (**Figure 2.2**) allows the gel to travel, but retain its position once injected. Cross-linking between HA-NHS and locally available primary amines may further increase retention of transplanted cells locally, as the adhesive properties of NHS-conjugated polymers has been previously established [93]. Although subfascial injection was established as an efficient method to ensure sufficient spreading of the hydrogel (**Figure 2.4**), intramuscular injection of the hydrogel may allow for further dispersion and delivery of transplanted cells. Also, since myostatin inhibition has been previously demonstrated to have positive effects on skeletal muscle stem cell transplantation [109], future potential studies could

synergistically utilize both hydrogel and the myostatin inhibitor RK35 to further promote the engraftment efficiency of transplanted cells.

Dystrophin-restored fibers and Pax7<sup>+</sup> / human Lamin A+C<sup>+</sup> co-stained nuclei were observed histologically in long-term transplanted muscles (**Figure 4.5**), but they were relatively rare. Cross sections are only representative of a small portion of an entire muscle; some information may be lost due to sampling bias. Purely visual confirmation of human muscle fiber formation also may not completely differentiate between true *de novo* donor-derived human muscle fibers and hybrid fibers formed with host muscle, originating due to ineffective ablation of satellite cell populations via irradiation or incomplete myotoxin injury. Whole-muscle outcomes of engraftment such as flow cytometry for GFP-labeled progenitor cells or Western blotting to precisely quantify levels of restored Dystrophin [110] may present a more representative evaluation of engraftment efficiency. Additionally, harvesting transplanted muscles at shorter or longer-term timepoints may be required to fully appreciate the effects of the hydrogel on donor-driven repair and regeneration. In the longer term, functional outcomes such as electrophysiology or whole-animal studies could also be utilized [103]. Still, despite the phenotypic severity of the *mdx*-5<sup>Cv</sup> mouse model [105], additional injury may be necessary to further elucidate the differences between treated groups.

Some limitations do exist with the transplanted human pluripotent stem cell-derived myoblasts utilized in this study. Although they form myofiber-like structures that express human laminin (**Figures 4.1-4.2**), the expression of sarcolemmal proteins such as human Dystrophin (**Figures 4.2, 4.5**) and human Collagen IV (data not shown) remain extremely limited by comparison. The cells in this study were injected after weeks of culture post-derivation without any intermediate purification steps; these cells are technically a heterogeneous population, the transplantation of which may decrease myogenic efficiency, and has had some unintended consequences in the form of possible transdifferentiation *in situ* leading to the formation of counterproductive non-muscular hypertrophy in some cases (data not shown). Purification of these cell populations prior to injection, potentially utilizing GFP or other markers, could potentially yield increased myogenic efficiency upon transplantation *in vivo*.

## Figures

## **Chapter 5: Conclusions and Future Directions**

## Conclusions

In this body of work, the principles of biomaterials and tissue engineering were applied to develop a regenerative medicine strategy for the treatment of DMD. We created an injectable biomaterial, known as a hydrogel, with the goal of utilizing it as a carrier to facilitate the delivery of growth factors and muscle progenitor cells in murine models of Duchenne Muscular Dystrophy. The hydrogel is composed of hyaluronic acid succinimidyl succinate (HA-NHS), a modified form of the glycosaminoglycan functionalized with *N*-hydroxysuccinimide groups to promote crosslinking to local primary amines and subsequent hydrogel formation. This was combined with decellularized porcine skeletal muscle extracellular matrix (M-ECM), a material noted for its utility in tissue engineering applications and its ability to modulate type 2 immune responses to promote pro-regenerative outcomes in skeletal muscle.

HA-NHS and M-ECM combined to form a hydrogel at physiologic temperatures *in vitro*, as determined by time sweep rheology. The hydrogel was determined to be cytocompatible *in vitro* when immortalized human myoblasts were cultured on the material over the course of four days. The hydrogel demonstrated excellent injectability and spreading when injected into the subfascial space above mouse tibialis anterior and quadriceps muscles, and was shown to degrade *in situ* over the course of 21 days. Additionally, the hydrogel promoted the controlled release of incorporated myostatin inhibitors *in vitro* and increase their bioactivity *in vivo*, both over the course of five days.

Given the role of the immune system in shaping the course of skeletal muscle repair, the immunomodulatory properties of the hydrogel were evaluated. Immunofluorescence-labeled cryosections from wild type and dystrophic muscles revealed the elevated presence of Fizz1<sup>+</sup> macrophages in hydrogel-injected muscles when compared to saline. This was further confirmed by flow cytometry, which verified elevated levels of CD206<sup>+</sup> macrophages in hydrogel-injected wild type and dystrophic mice. Furthermore, elevated levels of the pro-regenerative type 2 cytokine interleukin-4 were observed in the inguinal lymph nodes of hydrogel-injected wild type and dystrophic mice. However, increased expression of the inflammation-mediating cytokine interleukin-10 was only observed in the inguinal lymph nodes of wild type hydrogel-injected mice.

The immunomodulatory properties of the hydrogel were further characterized by evaluating its individual components (HA-NHS, M-ECM) in dystrophic mice. Additionally, the potential immunomodulatory effects of myostatin inhibition were evaluated by analyzing the immune microenvironment of dystrophic mice injected with RK35 alone or RK35 in hydrogel. Immunofluorescence analysis revealed the presence of Fizz1<sup>+</sup> macrophages in M-ECM, hydrogel, and hydrogel+RK35 injected dystrophic mouse muscles. Cytometric analysis confirmed the elevated presence of CD206<sup>+</sup> macrophages in hydrogel and hydrogel+RK35 injected mice, and inguinal lymph node cytokine analysis revealed significantly elevated levels of interleukin-4 in M-ECM, hydrogel, and hydrogel+RK35 injected mice. Analysis of CD3<sup>+</sup> T cell population subsets revealed significant increases in the CD4<sup>+</sup> T helper cells and Foxp3<sup>+</sup> regulatory T cells in mice

injected with hydrogel+RK35. Increases in these key cell populations, which mediate effective skeletal muscle regeneration, were not observed with any of the individual hydrogel components, the hydrogel alone, or the myostatin inhibitor alone, suggesting a novel immunomodulatory functionality present with the combination of biomaterials implantation and myostatin inhibition in dystrophic mice.

The multifunctionality of the hydrogel was further evaluated by utilizing it as an injectable carrier for transplanted skeletal muscle stem cells. Human embryonic stem cells derived to the myogenic lineage via treatment with CHIR99021 and DAPT were transplanted into immunodeficient mice and verified to form human muscle fibers *in situ*, reoccupy the endogenous skeletal muscle progenitor cell niche, and promote long-term repair after injury. Short-term evaluation of the hydrogel as a cell carrier revealed increased numbers of immortalized human myoblasts transplanted with the hydrogel visible in serial cryosections after 7 days, and increased numbers of GFP<sup>+</sup> human embryonic stem cell derived myoblasts present in single cell suspensions derived from hydrogel-injected muscles 10 days after transplantation. A longer-term study of hESC-derived myoblasts transplanted into immunodeficient dystrophic mice revealed their capability to reoccupy the satellite cell niche after 4 months, and increased numbers of human Laminin<sup>+</sup> and Dystrophin<sup>+</sup> fibers in hydrogel-transplanted muscles.

## Future Directions

Given the interdisciplinary nature of this project, which lies at the interface of bioengineering and skeletal muscle biology, numerous potential future experimental directions remain. Proteomic analysis of extracellular matrix components of the hydrogel [111] could be used to isolate the specific factors that promote regeneration *in vivo*. Delivery of RK35 with HA-NHS or M-ECM alone could be used to not only determine mechanisms of increased bioactivity, but potential synergistic immunomodulatory effects as well. Efficacy of myostatin inhibitor delivery could be further assessed by morphometric, physiologic, or functional assays of RK35-injected muscles, and longer-term studies could further clarify the effect of the hydrogel. Co-administration of hydrogel and RK35 in other form factors such as systemic, intramuscular, or extended-release formulations may help verify the role of sustained myostatin inhibition on the immune microenvironment in DMD.

Immunomodulatory evaluation of the materials and myostatin inhibitor was only performed at 1 week; shorter or longer timepoints where different populations such as neutrophils, eosinophils, or regulatory T cells predominate could clarify the effects of both injected components on the entire course of immune-mediated skeletal muscle regeneration. Any one of these populations could also be isolated and subjected to transcriptome analysis. Systemic effects of these materials on distal lymph nodes or distal muscles such as the diaphragm (the most profoundly affected muscle in dystrophic mice) could also be evaluated. These materials were also only tested in

healthy wild type and dystrophic animals; various models of muscle injury [102] could be applied in conjunction with these genotypes in order to reveal defects in regeneration that could be positively mediated with the myostatin inhibitor or hydrogel.

Eventually, future therapeutic developments could include combinatorial delivery of muscle progenitor cells and myostatin inhibitors with the hydrogel, potentially increasing the efficacy of cell therapy for DMD. Transplantation of progenitor cells with reporters to isolate specific cell populations such as Pax7 could not only promote transplantation efficacy, but also facilitate visualization and verification of engraftment. Given the profound effects of the immune system on skeletal muscle and local muscle progenitor cells, a hydrogel such as the one described here could not only create a microenvironment in which transplanted cells could survive and thrive, but also shape the host immune microenvironment to promote donor cell engraftment and myofiber formation *in situ*. The use of mouse myoblasts in transplantation assays could allow for the use of immunocompetent mice, allowing for elucidation of the direct effects of immunomodulation on cell transplantation efficiency. Overall, this study represents the first observation of the combined effect of biomaterials and myostatin inhibition on the musculoskeletal immune microenvironment, providing novel insights into potential immunomodulatory therapies for Duchenne Muscular Dystrophy.

## Curriculum Vitae

KENNETH M. ESTRELLAS  
Kenneth.estrellas@gmail.com

### Education

2011-17: JOHNS HOPKINS UNIVERSITY. BALTIMORE, MD. PhD Candidate, Graduate Training Program in Cellular and Molecular Medicine.  
Dissertation: Development of a Regenerative Medicine Strategy for the Treatment of Duchenne Muscular Dystrophy.

2011: BROWN UNIVERSITY. PROVIDENCE, RI. Master of Science in Biology.  
Dissertation: Synthesis and Evaluation of Time-Dependent Mucoadhesion of Novel Bioadhesive Polymers.

2010: BROWN UNIVERSITY. PROVIDENCE, RI. Bachelor of Science in Biology with Honors.  
Thesis: Fabrication of Double-Walled Nanospheres by Sequential Phase Inversion Nanoencapsulation.

2010: BROWN UNIVERSITY. PROVIDENCE, RI. Bachelor of Arts in Economics.

### Research Experience

2012-2017: PhD Candidate. Johns Hopkins University. Baltimore, MD.  
Co-Mentors: Dr. Kathryn Wagner, MD PhD (Director, Center for Genetic Muscle Disorders, Kennedy Krieger Institute) and Dr. Jennifer Elisseeff, PhD (Director, Translational Tissue Engineering Center, Johns Hopkins School of Medicine).  
Development of biomaterial hydrogel for use in myogenic progenitor cell transplantation and growth factor delivery for the treatment of muscular dystrophies.  
Analysis of regenerative capacity of transplanted human muscle stem cells.  
Determination of immunomodulatory properties of implanted biomaterials.

2011: Rotation Student. Johns Hopkins University. Baltimore, MD.  
Mentor: Dr. Charles Rudin, MD PhD (Co-Director, Druckenmiller Center for Lung Cancer Research, Memorial Sloan Kettering Cancer Center).  
Investigation of the role of autophagy and apoptosis in small cell lung cancer.

2009–2011: Research Assistant. Brown University. Providence, RI.

Mentor: Dr. Edith Mathiowitz PhD (Director, Biotechnology Graduate Program, Brown University). Fabrication and characterization of double-walled polymer nanospheres for use in drug delivery. In vivo rodent studies of uptake, biodistribution, and bioadhesion. 2008–2009: Research Assistant. Brown University. Providence, RI.  
Mentor: Dr. Sorin Istrail PhD (Professor, Computer Science, Brown University).  
Study of cis -regulation of transcription factor expression and conversion of genetic annotation data from primary literature into browser-based database (Project CYRENE).

### Publications

K.N. Sadtler, B.W. Allen, K.M. Estrellas, J.D. Powell, F. Hosseau, D.M. Pardoll, J.H. Elisseeff. The Scaffold Immune Microenvironment: Biomaterial-Mediated Immune Polarization in Traumatic and Non-Traumatic Applications. Tissue Engineering Part A. October 2016.

I.Y. Choi, H.T. Lim, K.M. Estrellas, J. Mula, T.V. Cohen, Y Zhang, C.J. Donnelly, J.P Richard, Y.J. Kim, H. Kim, Y. Kazuki, M. Oshimura, H. Li, A. Hotta, J. Rothstein, N. Margakis, K.R. Wagner, G. Lee. Concordant but varied phenotypes among patient-specific myoblasts of Duchenne muscular dystrophy revealed by human iPSC-based model. Cell Reports. May 2016.

D.Y. Cho, K.M. Estrellas, C. Tian, J. Reineke, E. Mathiowitz. A Novel Method for the Fabrication of Double-Walled Nanospheres by Sequential Phase Inversion Nanoencapsulation. 37th Annual Meeting and Exposition of the Controlled Release Society. Portland, OR. July 2010.

D.Y. Cho, C. Tian, K.M. Estrellas, E. Mathiowitz. Effect of Encapsulation Method on Protein Loaded Nanospheres Fabricated by Phase Inversion Nanoencapsulation. 37th Annual Meeting and Exposition of the Controlled Release Society. Portland, OR. July 2010.

### Technical Skills

Rodents: Small Rodent Surgical Models (Cell Transplantation, Hydrogel/Biomaterials Implantation), Small Rodent Injury Models (Volumetric Muscle Defect, Muscle Myotoxins (Cardiotoxin, Notexin, Barium Chloride), Muscle Irradiation), Small Rodent Anesthesia (Isoflurane, Ketamine/Xylazine), Small Rodent Drug Administration (Intraperitoneal, Subcutaneous, Intramuscular), Small Rodent Functional Testing

(Treadmill Exhaustion, Grip Strength), Small Rodent Breeding/Husbandry and Genotyping.

Cellular: Cell Isolation (Muscle Progenitors, Lymphoid/Myeloid Immune Cells), Multiplex/Multicolor Flow Cytometry Staining, Cell/Tissue Culture, Cell Viability (Live/DEAD), Cell Proliferation (MTS/MTT, AlmarBlue/PrestoBlue).

Genetic: RNA Isolation, RNA Quantification (Nanodrop), cDNA Synthesis, Quantitative RT-PCR (qPCR), DNA Isolation, PCR.

Protein: Protein Isolation, Protein Quantification (BCA), Western Blotting, ELISA.

Histology: Cryosectioning, Multiplex Immunofluorescence, Hematoxylin & Eosin (H&E), Masson's Trichrome.

Imaging: Multiplex/Multicolor Epifluorescence Microscopy (Zeiss Axio Imager M2), Multiplex/Multicolor Confocal Microscopy (Olympus FV1000), Brightfield Microscopy (Zeiss Axio Imager M2).

Muscle: Cross-Sectional Area Muscle Regeneration Analysis, Muscle Histology and Immunofluorescence.

Bioengineering: Cell Encapsulation, Animal Tissue Decellularization, Hydrogel Fabrication, Polymer Synthesis, Hydroxamate Assay, Rheology, Differential Scanning Calorimetry.

Software: Zeiss AxioVision, Olympus FluoView, Microsoft Image Composite Editor (ICE), GraphPad Prism, Microsoft Office, EndNote, Adobe Photoshop, iMovie, Sony Vegas.

### Honors/Awards

2016 Maryland State Champion, 3 Minute Thesis Competition - University of Maryland. Baltimore, MD. Summary of PhD thesis in three minutes. Explanation of complex scientific concepts to general audience.

2016 3rd Place Winner, 3 Minute Thesis Competition - Johns Hopkins University. Baltimore, MD. Summary of PhD thesis in three minutes. Explanation of complex scientific concepts to general audience.

2016 1st Place Winner, Baltimore Underground Science Space x Project Bridge Science Slam. Baltimore, MD. Summary of PhD thesis in three minutes. Explanation of complex scientific concepts to general audience.

2010 Graduate Honors, ScB Biology. Brown University. Providence, RI. Honors conferred upon Brown University ScB Biology graduates upon completion of thesis.

2010 The Alfred H. Joslin Award for Student Leadership and Involvement. Brown University. Providence, RI. Awarded to graduating seniors who have demonstrated extensive student leadership and involvement.

### Leadership Experience

2015–17 Graduate Student Mentor, JHU Undergraduate Neuroscience Program. Baltimore, MD. Individualized mentorship / research training of JHU undergraduate student, Lindsay Cheu.

2015–16 Co-Chair, Brown University Alumni Interviewing Program, Area 210. Baltimore, MD. Organized admissions interviews for ~300 Baltimore area high school applicants to Brown University.

2014–17 Director of Operations, Baltimore Dance Crews Project Collective. Baltimore, MD. Scheduled rehearsals & logistical support for urban dance organization.

2011–14 Workshop Coordinator/Instructor, Baltimore Dance Crews Project. Baltimore, MD. Planned beginner-advanced urban dance workshops for public audiences.

2009-11 Primary Organizer, Free Open Hip Hop Dance Workshops. Brown University. Providence, RI. Planned intermediate-advanced urban dance workshops for public audiences.

2009-11 Co-Director, imPulse Dance Company. Brown University. Providence, RI. Creative and logistical direction of a collegiate urban dance organization.

2008–09 Co-Founder / Organizer, “Dancing With The Professors.” Brown University. Providence, RI. Co-developed charity event pairing Brown professors with Brown Ballroom Dance Team members.

2007–08 Co-President, Filipino Alliance. Brown University. Providence, RI. Creative and logistical direction of organization dedicated to spreading awareness of Filipino culture.

## Professional Experience

2016            Equity Research Extern. T. Rowe Price / BCI Equity Research Externship. Baltimore, MD. Performed due diligence on mid-cap life sciences companies and formulated biotech stock pitch.

2013            Consulting Case Competition. Johns Hopkins University Graduate Consulting Club. Baltimore, MD. Participated in team-based business consulting life sciences case competition.

2010–11        NSF EPSCoR Entrepreneurial Fellow. Slater Technology Fund. Providence, RI. Biopharmaceutical venture capital development and startup formation.

2008–11        Intern. New Age Marketing, Inc. Conway, NH. Viability assessment of college marketing methods; production of training materials.
